Concurrency Control-Timestamp Ordering

Multiversion Schemes

- Multiversion schemes keep old versions of data item to increase concurrency.
 - Multiversion Timestamp Ordering
 - Multiversion Two-Phase Locking
- Each successful write results in the creation of a new version of the data item written.
- Use timestamps to label versions.
- When a read(Q) operation is issued, select an appropriate version of Q based on the timestamp of the transaction, and return the value of the selected version.
- reads never have to wait as an appropriate version is returned immediately.

Multiversion Timestamp Ordering

- Each data item Q has a sequence of versions $<Q_1, Q_2, \ldots, Q_m >$. Each version Q_k contains three data fields:
 - **Content** –– the value of version Q_k .
 - **W-timestamp**(Q_k) -- timestamp of the transaction that created (wrote) version Q_k
 - **R-timestamp**(Q_k) -- largest timestamp of a transaction that successfully read version Q_k
- when a transaction T_i creates a new version Q_k of Q_i , Q_k 's W-timestamp and R-timestamp are initialized to TS(T_i).
- R-timestamp of Q_k is updated whenever a transaction T_j reads Q_k , and $TS(T_j) > R-$ timestamp (Q_k) .

Multiversion Timestamp Ordering (Cont) multiversion timestamp scheme presented next ensures

- serializability.
- Suppose that transaction \mathcal{T}_i issues a read(Q) or write(Q) operation. Let Q_k denote the version of Q whose write timestamp is the largest write timestamp less than or equal to $TS(T_i)$.
 - 1. If transaction T_i issues a **read**(Q), then the value returned is the content of version Q_k .
 - 2. If transaction T_i issues a write (Q), and if TS(T_i) < Rtimestamp(Q_k), then transaction T_i is rolled back. Otherwise, if TS(T_i) = W-timestamp(Q_k), the contents of Q_k are overwritten, otherwise a new version of Q is created.
- Reads always succeed; a write by T_i is rejected if some other transaction T_i that (in the serialization order defined by the timestamp values) should read T_i 's write, has already read a version created by a transaction older than T_{i} .

Multiversion Two-Phase Locking

- Differentiates between read-only transactions and update transactions
- Update transactions acquire read and write locks, and hold all locks up to the end of the transaction. That is, update transactions follow rigorous twophase locking.
 - Each successful write results in the creation of a new version of the data item written.
 - each version of a data item has a single timestamp whose value is obtained from a counter ts-counter that is incremented during commit processing.

Read-only transactions are assigned a timestamp by reading the current value of ts-counter before they start execution; they follow the multiversion timestamp-ordering protocol for performing reads.

Multiversion Two-Phase Locking

- it obtains a shared lock on it, and reads the latest version.
- When it wants to write an item, it obtains X lock on; it then creates a new version of the item and sets this version's timestamp to ∞ .
- ▶ When update transaction *T_i* completes, commit processing occurs:
 - T_i sets timestamp on the versions it has created to ts-counter + 1
 - *T_i* increments **ts-counter** by 1
- Read-only transactions that start after T_i increments tscounter will see the values updated by T_i .
- Read-only transactions that start before T_i increments the
- **ts-counter** will see the value before the updates by T_{j} .
- Only serializable schedules are produced.

Deadlock Handling

Consider the following two transactions:

7 ₁ :	write (X)	<i>T</i> ₂ :	write(<i>Y</i>)
	write(<i>Y</i>)		write(<i>X</i>)

Schedule with deadlock

-		
2		

lock-X on *X* write (*X*)

lock-X on Y write (X) wait for **lock-X** on X

wait for lock-X on Y

Deadlock Handling

- System is deadlocked if there is a set of transactions such that every transaction in the set is waiting for another transaction in the set.
- Deadlock prevention protocols ensure that the system will never enter into a deadlock state. Some prevention strategies :
 - Require that each transaction locks all its data items before it begins execution (predeclaration).
 - Impose partial ordering of all data items and require that a transaction can lock data items only in the order specified by the partial order (graph-based protocol).

More Deadlock Prevention Strategies

- Following schemes use transaction timestamps for the sake of deadlock prevention alone.
- wait-die scheme non-preemptive
 - older transaction may wait for younger one to release data item. Younger transactions never wait for older ones; they are rolled back instead.
 - a transaction may die several times before acquiring needed data item
- wound-wait scheme preemptive
 - older transaction *wounds* (forces rollback) of younger transaction instead of waiting for it. Younger transactions may wait for older ones.
 - may be fewer rollbacks than wait-die scheme.

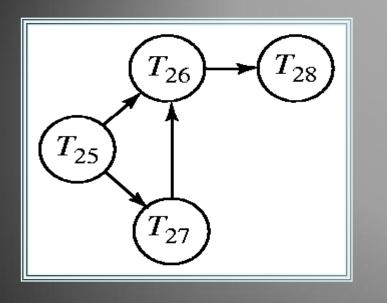

Deadlock prevention (Cont.)

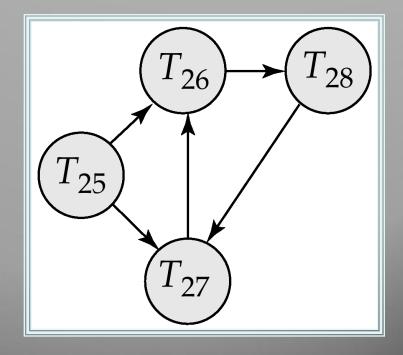

- Both in *wait-die* and in *wound-wait* schemes, a rolled back transactions is restarted with its original timestamp. Older transactions thus have precedence over newer ones, and starvation is hence avoided.
- Timeout-Based Schemes :
 - a transaction waits for a lock only for a specified amount of time. After that, the wait times out and the transaction is rolled back.
 - thus deadlocks are not possible
 - simple to implement; but starvation is possible. Also difficult to determine good value of the timeout interval.

Deadlock Detection

- Deadlocks can be described as a wait-for graph, which consists of a pair G = (V, E),
 - V is a set of vertices (all the transactions in the system)
 - *E* is a set of edges; each element is an ordered pair $T_i \rightarrow T_i$.
- If $T_i \rightarrow T_j$ is in E, then there is a directed edge from T_j to T_j , implying that T_j is waiting for T_j to release a data item.
- When T_i requests a data item currently being held by T_j, then the edge T_i T_j is inserted in the wait-for graph. This edge is removed only when T_j is no longer holding a data item needed by T_j.
- The system is in a deadlock state if and only if the wait-for graph has a cycle. Must invoke a deadlock-detection algorithm periodically to look for cycles.

Deadlock Detection (Cont.)

Wait-for graph without a cycle

Wait-for graph with a cycle

Deadlock Recovery

When deadlock is detected :

- Some transaction will have to rolled back (made a victim) to break deadlock. Select that transaction as victim that will incur minimum cost.
- Rollback -- determine how far to roll back transaction
 - Total rollback: Abort the transaction and then restart it.
 - More effective to roll back transaction only as far as necessary to break deadlock.
- Starvation happens if same transaction is always chosen as victim. Include the number of rollbacks in the cost factor to avoid starvation

Insert and Delete Operations

If two-phase locking is used :

- A delete operation may be performed only if the transaction deleting the tuple has an exclusive lock on the tuple to be deleted.
- A transaction that inserts a new tuple into the database is given an X-mode lock on the tuple

Insertions and deletions can lead to the phantom phenomenon.

 A transaction that scans a relation (e.g., find all accounts in Perryridge) and a transaction that inserts a tuple in the relation (e.g., insert a new account at Perryridge) may conflict in spite of not accessing any tuple in common.

 If only tuple locks are used, non-serializable schedules can result: the scan transaction may not see the new account, yet may be serialized before the insert transaction.

Insert and Delete Operations

(Completransaction scanning the relation is reading information that indicates what tuples the relation contains, while a transaction inserting a tuple updates the same information.

- The information should be locked.
- One solution:
 - Associate a data item with the relation, to represent the information about what tuples the relation contains.
 - Transactions scanning the relation acquire a shared lock in the data item,
 - Transactions inserting or deleting a tuple acquire an exclusive lock on the data item. (Note: locks on the data item do not conflict with locks on individual tuples.)
- Above protocol provides very low concurrency for insertions/deletions.
- Index locking protocols provide higher concurrency while preventing the phantom phenomenon, by requiring locks on certain index buckets.

Index Locking Protocol

- Every relation must have at least one index. Access to a relation must be made only through one of the indices on the relation.
- A transaction T_i that performs a lookup must lock all the index buckets that it accesses, in S-mode.
- A transaction T_i may not insert a tuple t_i into a relation r without updating all indices to r.
- T_i must perform a lookup on every index to find all index buckets that could have possibly contained a pointer to tuple t_i, had it existed already, and obtain locks in X-mode on all these index buckets. T_i must also obtain locks in X-mode on all index buckets that it modifies.
- The rules of the two-phase locking protocol must be observed.

Weak Levels of Consistency

- Degree-two consistency: differs from twophase locking in that S-locks may be released at any time, and locks may be acquired at any time
 - X-locks must be held till end of transaction
 - Serializability is not guaranteed, programmer must ensure that no erroneous database state will occur]
- Cursor stability:
 - For reads, each tuple is locked, read, and lock is immediately released
 - X-locks are held till end of transaction
 - Special case of degree-two consistency

Weak Levels of Consistency in SQL

- SQL allows non-serializable executions
 - Serializable: is the default
 - Repeatable read: allows only committed records to be read, and repeating a read should return the same value (so read locks should be retained)
 - However, the phantom phenomenon need not be prevented
 - T1 may see some records inserted by T2, but may not see others inserted by T2
 - Read committed: same as degree two consistency, but most systems implement it as cursor-stability
 - Read uncommitted: allows even uncommitted data to be read

Concurrency in Index Structures

- Indices are unlike other database items in that their only job is to help in accessing data.
- Index-structures are typically accessed very often, much more than other database items.
- Treating index-structures like other database items leads to low concurrency. Two-phase locking on an index may result in transactions executing practically one-at-a-time.
- It is acceptable to have nonserializable concurrent access to an index as long as the accuracy of the index is maintained.
- In particular, the exact values read in an internal node of a B⁺-tree are irrelevant so long as we land up in the correct leaf node.
- There are index concurrency protocols where locks on internal nodes are released early, and not in a two-phase fashion.

Concurrency in Index Structures (Cont.)

- Example of index concurrency protocol:
- Use crabbing instead of two-phase locking on the nodes of the B⁺-tree, as follows. During search/insertion/deletion:
 - First lock the root node in shared mode.
 - After locking all required children of a node in shared mode, release the lock on the node.
 - During insertion/deletion, upgrade leaf node locks to exclusive mode.
 - When splitting or coalescing requires changes to a parent, lock the parent in exclusive mode.
- Above protocol can cause excessive deadlocks.
 Better protocols are available; see Section 16.9 for one such protocol, the B-link tree protocol
